Difference of degeneracy of the low-spin (LS) and high-spin (HS) states causes interesting entropy effects on spin-crossover phase transitions and charge transfer phase transitions in materials composed of the spin-crossover atoms. Mechanisms of the spin-crossover (SC) phase transitions have been studied by using Wajnflasz model, where the degeneracy of the spin states (HS or LS) is taken into account and cooperative natures of the spin-crossover phase transitions have been well described. Recently, a charge transfer (CT) phase transition due to electron hopping between LS and HS sites has been studied by using a generalized Wajnflasz model. In the both systems of SC and CT, the systems have a high temperature structure (HT) and a low temperature structure (LT), and the change between them can be a smooth crossover or a discontinuous first order phase transition depending on the parameters of the systems. Although apparently the standard SC system and the CT system are very different, it is shown that both models are equivalent under a certain transformation of variables. In both systems, the structure of metastable state at low temperatures is a matter of interest. We study temperature dependence of fraction of HT systematically in a unified model, and find several structures of equilibrium and metastable states of the model as functions of system parameters. In particular, we find a reentrant type metastable branch of HT in a low temperature region, which would play an important role to study the photo-irradiated processes of related materials.

§1. Introduction

In the so-called spin-crossover atoms, e.g., Fe and Co, spin states of the atoms can be changed between the high-spin (HS) state and the low-spin (LS) state by small perturbations, such as changes of temperature and pressure and also photo-irradiation, etc. This change of spin state is called spin-crossover (SC) transition.[1)–41)] The HS state has a large number of degeneracy and it is favorable at high temperatures, while the LS state has low energy which is favorable at low tem-

peratures. The competition between the effects of degeneracy (the entropy) and of the energy provides interesting changes of structure of material.

From a view point of adiabatic energy levels of local structure of atoms, the population dynamics among states (HS, LS, and other excited states) under photo-irradiation has been studied by a kind of rate equation, which explains mechanism of transition among the LS and HS states.[15),16)] It has been also pointed out that cooperative interactions are important for SC transitions. With an aid of interaction between atoms, this transition can be either smooth crossover or discontinuous first order phase transition depending on the system parameters.[1)–4),21)–34),40),41)] This situation is well described by the Wajnflasz model.[40),41)] Control between the HS and LS states has been realized by photo-irradiation as the light-induced excited spin state trapping (LIESST),[13)–20),35)–39)] and structure of the metastable ordered state of the systems has become an important topic.[20),42)–45)]

Prussian blue analogues (PBAs), classified as molecule-based magnets,[46)–53)] show various photomagnetic phenomena.[54)–62)]Two-way photo-switching between magnetic and nonmagnetic states was observed in a Co-Fe Prussian blue analogue, $K_{0.2}Co_{1.4}Fe(CN)_6 6.9H_2O$,[55),56)] which has attract much interest. This photomagnetism is based on the charge-transfer-induced spin transition (CTIST) between two phases,[58)] e.g., one is the high temperature (HT) phase consisting mainly of the Co^{II}-Fe^{III} where Co^{II} is in the high spin state (HS, $S = 3/2$) and Fe^{III} is in the low spin state (LS, $S = 1/2$), and the other is the low temperature (LT) phase consisting mainly of the Co^{III}-Fe^{II} where Co^{III} is in the low spin state (LS, $S = 0$) and Fe^{II} is also in the low spin state (LS, $S = 0$). In this material, Co and Fe ions are antiferromagnetically coupled. Therefore, precisely speaking, it is a ferrimagnetic material. However, the spin-crossover transition occurs at the Co site, and if we take a unit of the pair atoms (Fe and Co), we may regard the transition as a generalized SC transition.

On the other hand, another type of phase transition due to the charge transfer (CT) was discovered in a mixed-valence iron complex $(n\text{-}C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$ ($dto = C_2O_2S_2$).[63)–65)] In this material, the charge transfer causes a change of degeneracy of atomic states, and a phase transition occurs between the high temperature (HT) and low temperature (LT) structures. In this system, the spin transition on each atom does not occur. However, the entropy effect has an important role for the structure change of electron configuration and nature of phase transition was explained by using a generalized Wajnflasz model.[65)] There, it was found that a metastable branch of HT exists at all the temperatures below the critical temperature. This behavior is qualitatively different from that in the standard model of SC transition. That is, because experimentally the fraction of HS shows a hysteresis loop in SC transitions, for SC transitions we have adopted a model where the metastable branch of HS terminates at a spinodal point, and below which the HS is unstable. In this model, it is difficult to explain the metastable behavior of photo-induced HS state at low temperatures. In order to overcome this difficulty, a dynamical effect has been introduced by adopting the so-called Arrhenius dynamics,[35)] which has explained successfully the fact that the HS state remains for a long time at low temperatures although it is unstable in a mean-field free energy.[37)–39)] On the other

hand, in the model of CT, the HT state is metastable at all the temperatures. Now, it is an interesting problem to study the relation between the both models.

In this paper, we will show that the both models are equivalent under a certain transformation of variable, and the unified model shows several qualitatively different structures of equilibrium and metastable states as a function of system parameters. In particular, a reentrant type metastable branch of HT in a low temperature region is discovered. The existence of this low temperature metastable structure would play an important role to study the photo-irradiated processes of related materials. Here, we mainly study the transition of spin states, e.g. HS $\Leftrightarrow$ LS. However, if we consider magnetic interaction between the spins, the structure of phase transition is modified. The magnetic effect has been studied for Co-Fe PBA.[38),39),43),44)] The magnetic phase transition in the CT system has been also studied.[65)–67)] The existence of the metastable states causes new variety of magnetic phase transition, which will be briefly discussed.

§2. Unified model

2.1. *Typical spin-crossover phase transition with a single hysteresis*

In order to describe the spin-crossover transition, the so-called Wajnflasz model has been adopted,[40),41)] where the HS state is represented by $s = 1$, and the LS state is represented by $s = -1$. It should be noted that the states $s_i = \pm 1$ have different degeneracy. Let the number of states of the HS state be $n_{\rm H}$, and that of the LS state $n_{\rm L}$. Let us review the Wajnflasz model briefly.[35)] The interaction among atoms is originated in the elastic interaction in the atomic structure.[25)] However, here it is simply modeled by a nearest-neighbor interaction between sites, and the Hamitonian has the following form

$$\mathcal{H}_{\rm W} = -J \sum_{<ij>} s_i s_j + D \sum_i s_i, \tag{2·1}$$

where J denotes the interaction between states of neighboring atoms, and D denotes the energy difference between HS and LS. Here we consider the case where $D > 0$, i.e., the LS state is energetically favorable. The partition function is given by

$$Z = {\rm Tr} e^{-\beta \mathcal{H}_{\rm W}} = \sum_{s_1=\pm 1}{}' \cdots \sum_{s_N=\pm 1}{}' \exp\left(\beta J \sum_{<ij>} s_i s_j - \beta D \sum_i s_i \right), \tag{2·2}$$

where $\sum'$ denotes that the summation is carried out over the degenerate states, i.e., summation over $n_{\rm H}$ states of $s_i = 1$ and $n_{\rm L}$ states of $s_i = -1$. Here, $\beta = 1/k_B T$, and N is the number of sites. This form is expressed by a non-degenerate Ising variable $\sigma_i = \pm 1$ as

$$Z = \sum_{\sigma_1=\pm 1} \cdots \sum_{\sigma_N=\pm 1} \exp\left(\beta J \sum_{<ij>} \sigma_i \sigma_j - \beta D \sum_i \sigma_i \right) \prod_i \left(n_{\rm H} \delta_{\sigma,1} + n_{\rm L} \delta_{\sigma,-1} \right). \tag{2·3}$$

We may rewrite the second factor as

$$n_{\rm H}\delta_{\sigma,1}+n_{\rm L}\delta_{\sigma,-1}=\sqrt{n_{\rm H}n_{\rm L}}e^{\frac{1}{2}\sigma\ln\frac{n_{\rm H}}{n_{\rm L}}}. \tag{2·4}$$

Now we have

$$Z=(n_{\rm H}n_{\rm L})^{\frac{N}{2}}\sum_{\sigma_1=\pm1}\cdots\sum_{\sigma_N=\pm1}\exp\left(\beta\left(J\sum_{<ij>}\sigma_i\sigma_j-\left(D-\frac{k_{\rm B}T}{2}\ln g\right)\sum_i\sigma_i\right)\right), \tag{2·5}$$

and

$$g=\frac{n_{\rm H}}{n_{\rm L}}. \tag{2·6}$$

Therefore the model (2·1) can be expressed by an effective Hamiltonian with a temperature dependent field

$$\mathcal{H}=-J\sum_{<ij>}\sigma_i\sigma_j+\left(D-\frac{k_{\rm B}T}{2}\ln g\right)\sum_i\sigma_i. \tag{2·7}$$

This form of Hamiltonian is called Wajnflasz model.

Here, it should be noted on a characteristic property of this model. At high temperatures, $k_{\rm B}T>2D/\ln g$, the term of the effective field ($H_{\rm eff}=-D+k_{\rm B}T\ln g/2$) is positive, and thus the spins has a positive expectation value, $\langle\sigma_i\rangle>0$. On the other hand, at low temperatures, $k_{\rm B}T<2D/\ln g$, $\langle\sigma_i\rangle<0$. Let us define the marginal temperature T_0 to be

$$k_{\rm B}T_0=\frac{2D}{\ln g}, \tag{2·8}$$

where $\langle\sigma_i\rangle=0$. If T_0 is larger than the critical temperature $T_{\rm IC}$ of the corresponding Ising model

$$\mathcal{H}=-J\sum_{<ij>}\sigma_i\sigma_j, \tag{2·9}$$

that is,

$$T_0>T_{\rm IC}, \tag{2·10}$$

then the change of the magnetization is smooth. On the other hand, if

$$T_0<T_{\rm IC}, \tag{2·11}$$

then a discontinuous change occurs, which means the first order phase transition takes place.

A typical example of the hysteresis obtained by a kind of mean field analysis is schematically depicted in Fig. 1. So far, the experimental results of the first order phase transition have been explained by this type of temperature dependence of order parameter $f_{\rm HS}$ ($=(\langle\sigma_i\rangle+1)/2$) which is the fraction of the atoms in the HS state. In this figure, the HS state becomes unstable at a temperature T' denoted by a dotted line. Below this temperature, the HS state is unstable. Thus, it seems difficult to have a long-lived HS state at low temperatures. In Co-Fe PBA, however, the

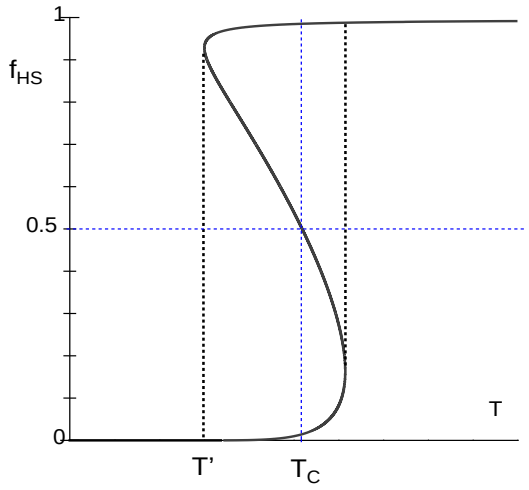

Fig. 1. Schematic temperature dependence of a solution of the self-consistent equation of a mean-field theory for the high spin fraction q of models of SC transition with a hysteresis loop. The bold dotted curves denote the hysteresis region. The thin dotted line denotes the first order phase transition temperature where $q = 0.5$.

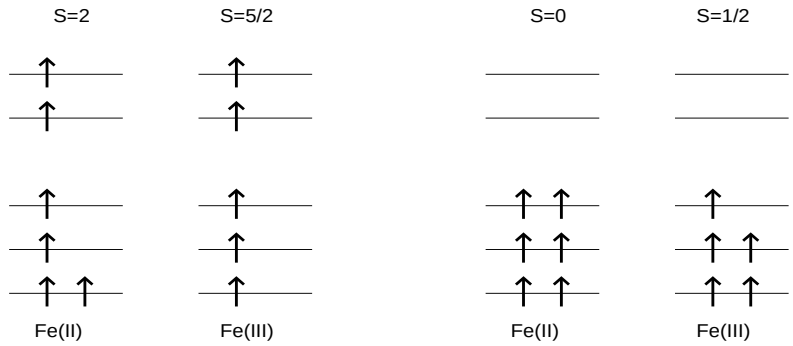
magnetic state exists for a long time after pumping by photo-irradiation. In order to explain this long-lived state we have introduced a mechanism of very slow dynamics, i.e., the so-called Arrhenius dynamics,[35),39)] where we assume an Arrhenius type relaxation time: $\tau \propto \exp(-E_0/k_{\rm B}T)$ with an appropriate value of E_0.

2.2. *Metastable structure of a charge transfer phase transition*

Contrary to the above mentioned behavior, we have found a case where the static metastability exists in the study of the charge transfer transition in material $(nC_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$ (dto=$C_2O_2S_2$).[63)–65)] Here, let us consider this charge transfer transition. This material consists of bipartite lattice. At one of the sublattices, Fe is surrounded by sulphur atoms where Fe is always in the low spin state (LS), and at the other sublattice Fe is surrounded by oxygen atoms where Fe is always in the high spin state (HS). We call the former 'A-site' and the latter 'B-site'. Let the both sublattices have N sites. Fe^{II} has one more electron than Fe^{III}, and the difference between them can be expressed by the number of additional electron n_i which is 1 in Fe^{II} and 0 in Fe^{III}. Here, we consider the degeneracy of spin degree of freedom.[65)] At A-site, Fe^{II} is in the low spin state and $S = 0$ as depicted in Fig. 2 and thus the degeneracy is 1, and the spin of Fe^{III} is $S = 1/2$ and thus its degeneracy is 2. Similarly at B-site, $S = 2$ for Fe^{II} and $S = 5/2$ for Fe^{III}. In terms of $\{n_i\}$, the degeneracy is given as the following:

site	n	spin S	degeneracy
A	$n = 1$	0	$n_{\rm A1}$=1
A	$n = 0$	1/2	$n_{\rm A0}$=2
B	$n = 1$	2	$n_{\rm B1}$=5
B	$n = 0$	5/2	$n_{\rm B0}$=6



(a) High spin (HS) states (b) Low spin (LS) states

Fig. 2. Electron states of Fe^{II} and Fe^{III} (a) in the high spin (HS) state and (b) in the low spin (LS)state

Because the numbers of sites of Fe^{II} and Fe^{III} are the same, the total number of the additional electrons is N

$$\sum_i n_i = N. \tag{2·12}$$

In this material, electrons transfer between A and B sites. We have introduced the following Hamiltonian for this system

$$\mathcal{H}_{\rm CT} = \varepsilon \sum_{<ij>} n_i n_j + \Delta \sum_{i\in {\rm B}} n_i, \tag{2·13}$$

where ε represents the interaction between the electrons at nearest neighbor sites. $\Delta(>0)$ denotes a kind of local on-site energy. Because of this term, energetically electrons tend to stay at A-sites. If all the electrons are on A-sites, then the system does not cost energy due to Δ. Therefore, we define this state as the perfect LT state. Because of the difference of the degeneracy listed above, at high temperature, electrons tend to stay at B-sites. We express the degree of high temperature (HT) state by the number of electrons at B-sites

$$\langle n_{\rm B} \rangle = \frac{\sum_{i\in {\rm B}} n_i}{N}. \tag{2·14}$$

In the above choice of the degeneracy, $\langle n_{\rm B} \rangle$ is more than half at high temperatures. In the present model, no spin-crossover transition occurs by the electron transfer. However, the degeneracy of spins still plays an important role, and this model exhibits a first order phase transition.[65] In the mean field theory, the self-consistent equation for $q = \langle \sigma_{i\in {\rm B}} \rangle$ is given by

$$q = \tanh \left[\beta \left(\frac{z\varepsilon q}{4} - \frac{\Delta}{4} + k_{\rm B} T \ln(5/3) \right) \right], \tag{2·15}$$

where z is the number of the nearest neighbor sites and is 3 for the Honeycomb lattice. We depict the typical temperature dependence of solution of self-consistent

equation for $\langle n_{\rm B}\rangle = (q+1)/2$ in Figs. 3 for $\Delta = 1$ and 10. There, we fix ε to be 3. In Fig. 3(b), there are three solutions for q at low temperatures. There, the largest and smallest ones give stable solutions and the second one gives an unstable solution. By comparing the free energies corresponding to them, we find the first order phase transition point, which is T_0. In figures, the temperature where $\langle n_{\rm B}\rangle = 0.5$ is shown by a dotted lines. This temperature has the same physical meaning as to T_0 defined in (2·8) as will be shown in the following subsections.

Here we find again that there are cases where the change is smooth and discontinuous. However, in this charge transfer transition, the metastable branch of HT state remains until $T = 0$, i.e., HT state is metastable even at very low temperatures.

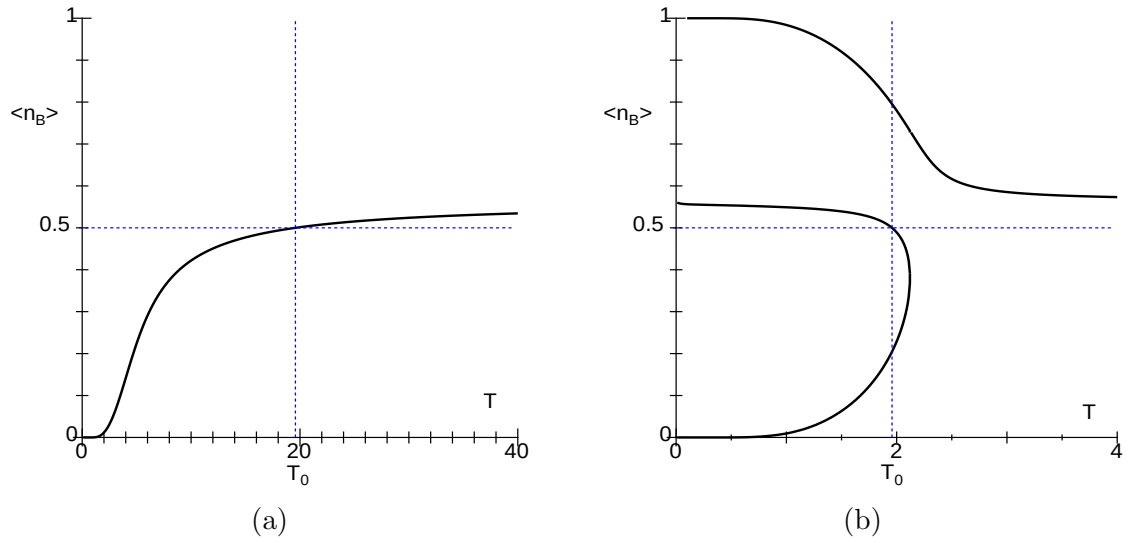


Fig. 3. Temperature dependence of fraction of the HT state $\langle n_{\rm B}\rangle$ for systems with $\varepsilon = 3$. (a) $\Delta = 10$ and (b) $\Delta = 1$. T_0 is the temperature where $\langle n_{\rm B}\rangle = 0.5$ and also it is the critical temperature in the case (b).

2.3. *Comparison*

In the two observations in the above SC and CT cases, there are qualitatively different temperature dependences of the free energy structure. Thus, it would be interesting to compare these two cases, and we will attempt to express this model (2·13) in the form of Wajnflasz model (2·7).

First, we transform the variable $n_i(= 0 \text{ or } 1)$ to $s_i(= -1 \text{ or } 1)$:

$$n_i = \frac{s_i + 1}{2}. \tag{2·16}$$

Here the constraint $(\sum_i n_i = N)$ becomes

$$\sum_i s_i = 0. \tag{2·17}$$

The Hamiltonian becomes

$$\mathcal{H} = \frac{\varepsilon}{4} \sum_{<ij>} (s_i + 1)(s_j + 1) + \frac{\Delta}{2} \sum_{i \in \mathrm{B}} (s_i + 1). \tag{2·18}$$

Making use of the constraint (2·17) we can rewrite it as

$$\mathcal{H} = \frac{\varepsilon}{4} \sum_{<ij>} (s_i + 1)(s_j + 1) + \frac{\Delta}{4} \left(\sum_{i \in \mathrm{B}} (s_i + 1) - \sum_{i \in \mathrm{A}} (s_j + 1) \right). \tag{2·19}$$

In order to have a ferromagnetic model, we perform a local gauge transformation: $\varepsilon \to -\varepsilon$, $s_i \to -S_i$ at A-site and $s_i \to S_i$ at B-site. Then we have

$$\mathcal{H} = -\frac{\varepsilon}{4} \sum_{<ij>} S_i S_j + \frac{\Delta}{4} \left(\sum_{i \in \mathrm{A}} S_i + \sum_{i \in \mathrm{B}} S_i \right). \tag{2·20}$$

Here we again use non-degenerate Ising variable σ_i. It should be noted that the numbers of degeneracy at A- and B-sites are different. However, using relations similar to (2·4), the numbers of degeneracy ($n_{\mathrm{A}1}$, $n_{\mathrm{A}0}$, $n_{\mathrm{B}1}$ and $n_{\mathrm{B}0}$) can be taken into account as

$$\mathcal{H} = -\frac{\varepsilon}{4} \sum_{<ij>} \sigma_i \sigma_j + \left(\frac{\Delta}{4} + \frac{1}{2} k_{\mathrm{B}} T \ln \frac{n_{\mathrm{A}1}}{n_{\mathrm{A}0}} \right) \sum_{i \in \mathrm{A}} \sigma_i + \left(\frac{\Delta}{4} - \frac{1}{2} k_{\mathrm{B}} T \ln \frac{n_{\mathrm{B}1}}{n_{\mathrm{B}0}} \right) \sum_{i \in \mathrm{B}} \sigma_i. \tag{2·21}$$

Using the constraint

$$\sum_{i \in \mathrm{A}} \sigma_i - \sum_{i \in \mathrm{B}} \sigma_i = 0, \tag{2·22}$$

we finally have

$$\mathcal{H} = -\frac{\varepsilon}{4} \sum_{<ij>} \sigma_i \sigma_j + \left(\frac{\Delta}{4} + \frac{1}{4} k_{\mathrm{B}} T \ln \frac{g_{\mathrm{A}}}{g_{\mathrm{B}}} \right) \sum_i \sigma_i, \tag{2·23}$$

where $g_{\mathrm{A}} = n_{\mathrm{A}1}/n_{\mathrm{A}0}$ and $g_{\mathrm{B}} = n_{\mathrm{B}1}/n_{\mathrm{B}0}$. Now, we have the same form as that of Wajnflasz model (2·7). Therefore, it is proved that the model (2·13) is equivalent to the model (2·1).

2.4. *T_0 for the CT transition*

In this formalism, we can make use of the relation (2·8) to distinguish the smooth and discontinuous changes. Here, the transition temperature T_0 is given by

$$k_{\mathrm{B}} T_0 = \frac{\Delta}{\ln \frac{g_{\mathrm{B}}}{g_{\mathrm{A}}}}. \tag{2·24}$$

Substituting the numbers of degeneracy, we have

$$k_{\mathrm{B}} T_0 = \frac{\Delta}{\ln \frac{5/6}{1/2}} = \frac{\Delta}{\ln 5/3} \simeq 1.958 \Delta. \tag{2·25}$$

In this subsection, we set $k_B = 1$.

In the case $\Delta = 10$, the condition (2·10) is satisfied. That is, in the honeycomb lattice, the critical temperature of the ferromagnetic Ising model is given by $k_B T_{\rm CI} = 3(\varepsilon/4)$ in the mean-field theory, and therefore, for $\varepsilon = 3$,

$$T_{\rm CI} = 0.75 \times 3 < T_0 = 1.958 \times 10, \tag{2·26}$$

and thus $\langle n_{\rm B} \rangle$ changes smoothly, which is depicted in Fig. 3(a). On the other hand, for $\Delta = 1$,

$$T_{\rm CI} = 0.75 \times 3 > T_0 = 1.958 \times 1, \tag{2·27}$$

and the transition is of the first order, which is depicted in Fig. 3(b).

2.5. *Monte Carlo study*

It should be noted that, although in the above we study the model in the mean-field approximation, the criterion whether the change of $\langle n_{\rm B} \rangle$ at T_0 is smooth or discontinuous, i.e., the relation between T_0 and $T_{\rm CI}$, also holds in the exact treatment. In the above treatment, the value of T_0 is given in the mean-field approximation because we studied the model in the mean-field approximation. However, in the exact treatment, T_0 is given by the critical temperature of the ferromagnetic Ising model:

$$T_{\rm CI} = \frac{2}{\ln(2+\sqrt{3})} \frac{\varepsilon}{4} \simeq 1.52 \times \left(\frac{\varepsilon}{4} \right). \tag{2·28}$$

In Fig.4, we depict the temperature dependence of $\langle n_{\rm B} \rangle$ studied by a Monte Carlo (MC) method for $\varepsilon = 3$ and 6 with $\Delta = 1$. Because we study the exact short range model in MC, we find exact properties in MC although it is numerically done. For $\varepsilon = 3$,

$$T_{\rm CI} = 1.52 \times (3/4) < T_0 = 1.958, \tag{2·29}$$

and then we indeed find that $\langle n_{\rm B} \rangle$ changes smoothly as plotted by the blue dots. For discontinuous change of $\langle n_{\rm B} \rangle$, the relation $T_0 < T_{\rm CI}$, i.e.,

$$1.958 < 1.52 \times (\varepsilon/4), \tag{2·30}$$

must be held. Therefore, in MC, ε must be larger than $5.15 (= 1.958 \times 4/1.52)$ for the discontinuous change. The temperature dependence of $\langle n_{\rm B} \rangle$ for $\varepsilon = 6$ is also plotted in Fig. 4 with black dots, where we find a discontinuous jump. Here, we changed the value of ε instead of Δ to have the same value of T_0 for the convenience to plot the data in a figure.

Monte Carlo simulations were performed on the honeycomb lattice of the size 32×32. The simulation started at $T = 0.125$ where $\langle n_{\rm B} \rangle \simeq 0$ in the equilibrium state. The temperature was increased up to $T = 4$. At each temperature, we performed 20000 Monte Carlo steps (MCS) for a transient process and then took data in the subsequence 100000MCS. Fluctuation of the data is smaller than the size of the dots.

We find that $\langle n_{\rm B} \rangle$ jumps at $T = 2.12$ although the exact critical point is $T_0 = 1.958$ which is indicated by the dotted line where $\langle n_{\rm B} \rangle = 0.5$. This shift of the jump is due to the hysteresis phenomenon associated with the first order phase transition.

After $T = 4$, the temperature was reduced. We find almost the same values of $\langle n_{\rm B} \rangle$ as those in the heating process above $T = 2.12$. However, it keeps a large value below this temperature, and stays in metastable HT state even below T_0. This metastability corresponds to the metastable solution found in the mean field theory. In the case $\varepsilon = 3$, no hysteresis is found.

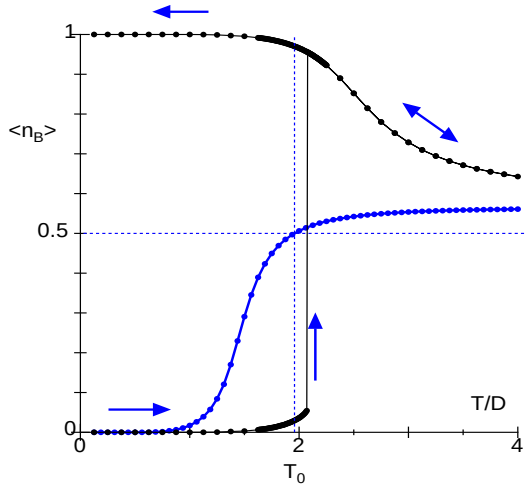

Fig. 4. Temperature dependence of fraction of the HT state $\langle n_{\rm B} \rangle$ for $\varepsilon = 3$ (blue dots) and 6 (black dots) studied by Monte Carlo simulations. Here, $\Delta = 1$.

In this way, we can know various properties of $\langle n_{\rm B} \rangle$ from the knowledge on the corresponding Ising model. For example, at the critical value of ε, $\langle n_{\rm B} \rangle$ shows a second order phase transition where

$$\langle n_{\rm B} \rangle - \frac{1}{2} \propto |T - T_0|^{\frac{1}{\delta}}, \quad \delta = 15 \tag{2·31}$$

and above the critical value of ε, $\langle n_{\rm B} \rangle$ changes discontinuously. The jump of $\langle n_{\rm B} \rangle$ is given by

$$\langle n_{\rm B}(T_0 + 0) - n_{\rm B}(T_0 - 0) \rangle \propto |\varepsilon - \varepsilon_c|^{\beta}, \quad \beta = \frac{1}{8}, \tag{2·32}$$

in the exact treatment and also in the Monte Carlo simulation. In the mean-field theory, on the other hand, the critical exponents are $\delta = 3$ and $\beta = 1/2$. In Fig. 5, the temperature dependences of $\langle n_{\rm B} \rangle$ at the critical value of ε are plotted for both cases studied in the mean-field theory (by bold curve) and in MC (by circles). Here it should be noted that $\langle n_{\rm B} \rangle$ shows a non-monotonic temperature dependence even in the case of the second order phase transition in MC.

§3. Classification of temperature dependence of the high-spin fraction

In the previous section, we have found the equivalence of the model of the SC transition and the model of the CT transition. In the SC case, the HS state becomes unstable at a temperature T' below the hysteresis loop. On the other hand, in the

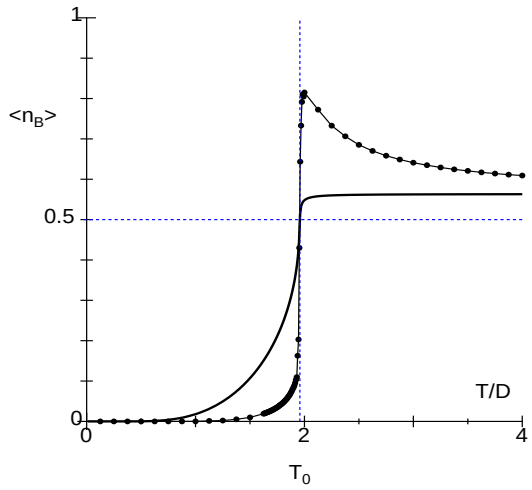

Fig. 5. Temperature dependence of fraction of the HT state $\langle n_{\rm B}\rangle$ at the critical value of ε studied by the mean-field theory $\varepsilon_{\rm C} = 3/(4\ln 10/3) = 2.61\cdots$ and by a Monte Carlo simulation $\varepsilon_{\rm C} = 1/(4\ln 10/3) = 5.18\cdots$. Here, $\Delta = 1$.

CT case the HT state remains metastable below T_0 until $T = 0$. These two observations suggest that there are qualitatively different temperature dependences of the free energy structure. By studying these structures, we can reach a comprehensive understanding of phase transitions of systems of spin-crossover atoms.

Here we study the model of the type of (2·7) with the variable $\sigma_i = \pm 1$

$$\mathcal{H} = -J\sum_{<ij>}\sigma_i\sigma_j + \left(D - \frac{k_{\rm B}T}{2}\ln g\right)\sum_i \sigma_i. \tag{3·1}$$

As has been mentioned in the previous section, the temperature T_0 where $\langle\sigma_i\rangle = 0$ is given by (2·8). Here, we define $D_{\rm C}$ as that the system exhibits a first-order phase transition when $D < D_{\rm C}$:

$$D_{\rm C} = \frac{k_{\rm B}T_{\rm C}}{2}\ln g. \tag{3·2}$$

Next, we consider the condition for the metastability of the HT state at the ground state. By flipping one spin in the configuration where all the spins are $+1$, the system gains the crystal field $-2D$, while it loses the exchange energy $2zJ$ where z is the number of nearest neighbors. Thus, if D is smaller than the critical value:

$$D_{\rm CG} = zJ, \tag{3·3}$$

the all up state is metastable at $T = 0$.

Let us study temperature dependence of solution(s)

$$q(T) = \langle\sigma_i\rangle \tag{3·4}$$

of mean-field self-consistent equation:

$$q = \tanh\left[\beta\left(Jzq - D + \frac{k_{\rm B}T}{2}\ln g\right)\right]. \tag{3·5}$$

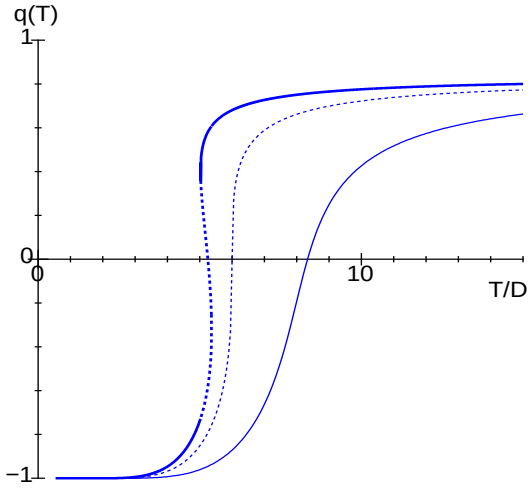

Fig. 6. Temperature dependences of $q(T)$ are depicted for $D = 10.0$ (thin solid curve), $D = 7.2$ (dashed curve), and $D = 6.3$ (bold solid and dashed curve). Here, $J = 1$ and $\alpha = 1.2$ ($g = e^{2.4}$).

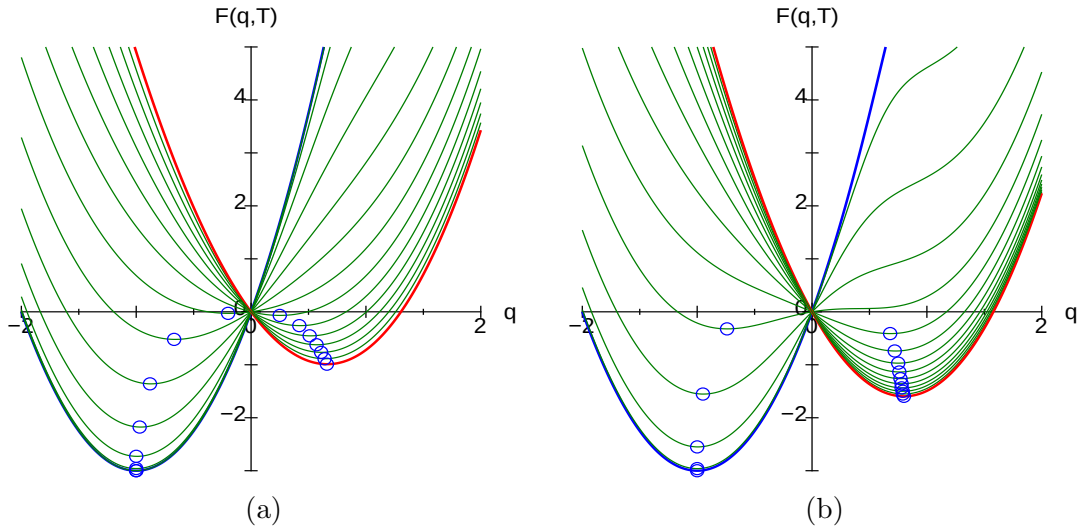

Fig. 7. Temperature dependence of the free energy of functions of q are depicted for (a) $D = 10.0$, and (b) $D = 6.3$. The temperature changes by 1 from $T = 15$ (red) to 1 (blue). Here $J = 1$ and $\alpha = 1.2$ ($g = e^{2.4}$). The open circles indicate extreme points of the free energy.

The free energy for the solution is given by

$$F(q) = \frac{1}{2}zJq^2 - k_{\rm B}T \ln \left[2\cosh \left(\frac{Jzq - D}{k_{\rm B}T} + \alpha \right) \right]. \tag{3·6}$$

Here, we adopt the following parameters

$$J = 1, \quad z = 6, \quad \text{and} \quad \alpha \equiv \frac{1}{2} \ln g = 1.2, \tag{3·7}$$

and here we take J as a unit of the energy. In the followings, we study the temperature dependence of $q(T)$ and its dependence on D.

3.1. *Large D behavior*

In Fig. 6, we show the temperature dependence of q for $D = 10$ by a thin solid curve where we find a smooth change of q, and corresponding temperature dependence of the free energy $F(q) - F(0)$ is depicted in Fig. 7(a). In the present case $D_{\rm C}$ is 7.2, below which the system shows a first-order phase transition. Temperature dependence of $q(T)$ for $D = 7.2$ is depicted by a dotted curve. The temperature dependence of q for $D = 6.3$ is depicted by bold solid and dashed curve, which shows a first order phase transition. The overhanging part is plotted by a bold dotted line. This temperature dependence corresponds to the standard phenomena of HS-LS transition shown in Fig. 1. Corresponding temperature dependence of the free energy is depicted in Fig. 7(b).

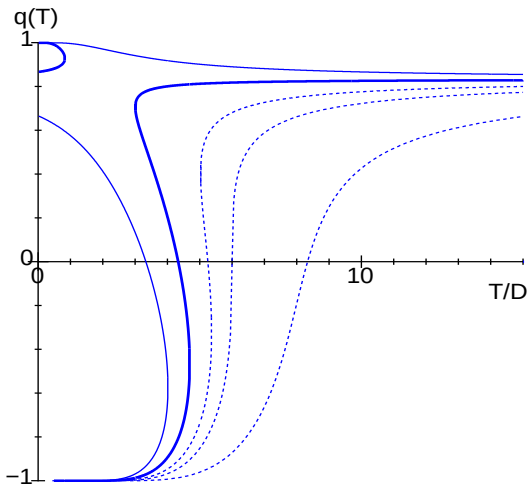

Fig. 8. Temperature dependences of q are depicted for $D = 5.2$ (bold solid curve) and $D = 4.0$ (thin solid curve). The dotted curves are $q(T)$ for $D = 10$, 7.2, and 6.3 which are depicted in Fig. 6. Here, $J = 1$ and $\alpha = 1.2$ ($g = e^{2.4}$).

In typical spin-crossover transitions, the ratio of the degeneracy g is considered to be rather large, and it causes the value of q in the high temperature limit

$$q(\infty) = \tanh(\alpha) = \frac{g-1}{g+1} \tag{3·8}$$

to be large.

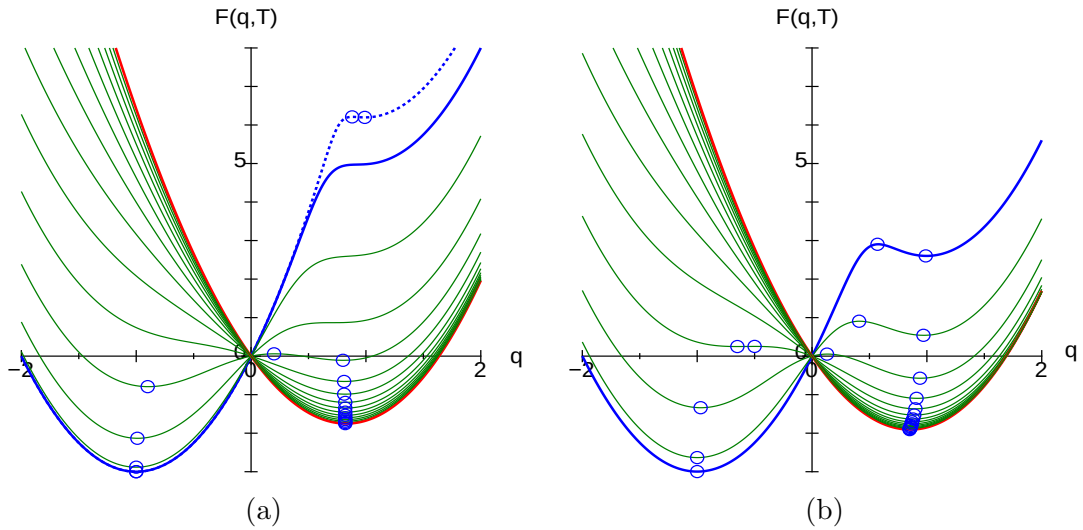

Fig. 9. Temperature dependence of the free energy of functions of q for (a) $D = 5.2$ and (b) $D = 4.0$. The temperature changes by 1 from $T = 15$ (red) to 1 (blue). The data for $T = 0.5$ is also plotted by a bold dotted blue curves. Here, $J = 1$ and $\alpha = 1.2$ ($g = e^{2.4}$).

3.2. *Hysteresis branch in low temperature region for the intermediate D*

If we take the value of D below $D_{\rm CG}$, we find a metastable branch appears at low temperatures. In Fig. 8, we show the temperature dependence of q for $D = 5.2$ by a bold curve, and corresponding temperature dependence of the free energy in Fig. 9(a). Here we find the free energy has a local minimum of HS at low temperatures. This low temperature metastable branch of HS may play an important role for the long-lived metastable state in Co-Fe PBA. In this case, the metastability of HS is intrinsic and if the initial state is set to be near the metastable point, the value of q is expected to move first to the metastable value and then relaxes to the LT state through a nucleation process. On the other hand, if there is no metastable branch at low temperatures as the case $D = 6.3$, the long-lived HS state must be purely due to the slow dynamics. In this case, q always moves to the 0. Checking this initial move of q, one may find which case is realized. It would be an interesting problem to determine that to which case individual materials belong.

3.3. *Small D behavior*

If we reduce D furthermore, e.g., $D = 4$, HT state becomes metastable at all temperatures as we depict in Fig. 8 by a thin curve. The free energy change of this case is plotted in Fig. 9(b). This case corresponds to the dependence found in CT transition as shown in Fig. 3. For $D = 4$, the high temperature branch connects to the metastable HT branch at low temperatures, which is topologically different from those of large values of D. It should be noted that in this case the potential barrier between the metastable HT state and the stable LT state shows a non-monotonic

dependence, and the metastable state easily relaxes to the stable LT state via a nucleation process in the intermediate temperature region. The dependence of the barrier is plotted in Fig. 10.

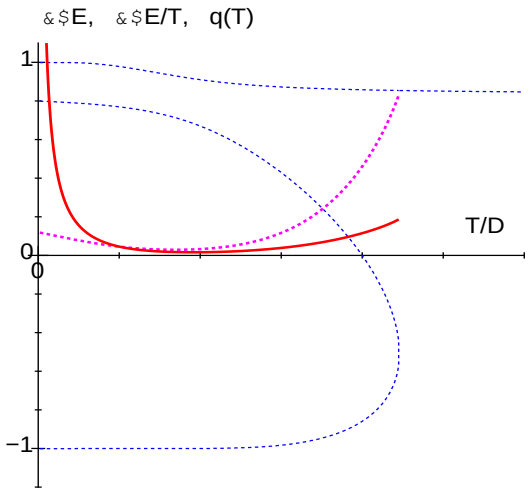

Fig. 10. Temperature dependence of the barrier height between the metastable HT state and the stable LT state for $D = 4.8$. The temperature dependence of $q(T)$ is also plotted by thin dotted curves. The energy barrier ΔE is depicted by the bold dotted curve, and $\Delta E/k_{\rm B}T$ is depicted by the bold curve. Here, $J = 1$ and $\alpha = 1.2$ ($g = e^{2.4}$).

3.4. *Topological change of the structure of solutions*

So far we found two regions of D. In the large D region the solution of HT state at high temperatures connects to the LT state at low temperatures. On the other hand, in the small D region, the solution of HT state at high temperatures remains until $T = 0$. There, a LT solution exists separately. Thus, there is a critical value of D between these two regions. We depict $q(T)$ at the critical value of D in Fig. 11. In the mean-field theory, $q(T)$ does not depend on the temperature at this marginal value of D. The values of $q(T)$ and the marginal D are found in the following analysis. If the following relations

$$q = \frac{D}{Jz} \quad \text{and} \quad q = \tanh\alpha, \tag{3·9}$$

hold, then from the self-consistent equation (3·5),

$$q = \tanh\left(\frac{Jzq - D}{k_{\rm B}T} + \alpha\right) \tag{3·10}$$

is always satisfied. From this relation, we find that the critical value of D is given by the equation:

$$D_{\rm CX} = zJ\tanh\alpha \tag{3·11}$$

and

$$q = \tanh\alpha. \tag{3·12}$$

Indeed the marginal value of D is given by

$$D_{\rm CX} = 6 \times \tanh(1.2) J = 5.00193 \cdots J. \tag{3·13}$$

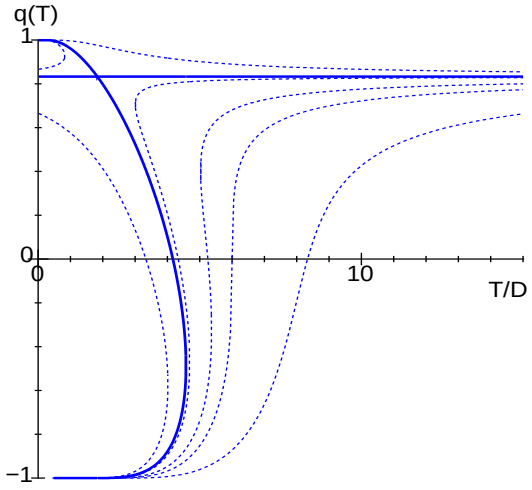

Fig. 11. Temperature dependence of $q(T)$ for $D = D_{\rm CX}$ (solid curve). The temperature dependence for the values studied previously are shown by dotted lines ($D = 10, 7.2, 6.3, 5.2$ and 4.0). Here, $J = 1$ and $\alpha = 1.2$ ($g = e^{2.4}$).

3.5. *Sequence of the types of structure*

Here we found three critical values of D. Finally let us point out the fact that the isolated low temperature metastable branch of HS exists for all the values of α. That is, in order to have the metastable state at low temperature, D must be smaller than $D_{\rm CG}$, i.e.,

$$D < zJ, \tag{3·14}$$

and in order to avoid that the solution of HT exists at all the temperatures, D must satisfy the condition

$$D < D_{\rm CX} = zJ \tanh \alpha. \tag{3·15}$$

Both conditions are compatible although the region of D is rather narrow for large α. In experiments, one may control the value of degeneracy by changing the pressure, etc. It would be very interesting to find the qualitative change of temperature dependence of metastable states which is found here.

§4. Summary and Discussion

In this paper, we studied models for phase transitions of systems consisting of spin-crossover atoms. We pointed out that the apparently different models for the spin-crossover transition and for the charge-transfer transition are equivalent, and

we comprehensively studied structures of stable and metastable states of the unified model. We found several qualitatively different ordering processes, and found critical values of D between different types of ordering processes. In particular, we found a metastable HS state at low temperatures which exists separately from the high temperate HS state. We find that a metastable HS state universally exists in the present type of models. This metastable HS state at low temperature would play an important in pumping process by photo-irradiation. The present study will be useful to classify the metastability in various photomagnetic materials where metastability will be investigated by photo-irradiation.

In Co-Fe PBA and CT materials, the system shows a magnetic ordering in addition to the spin structure change. There, we have to consider the magnetic interaction. Effect of the magnetic interaction on the combined ordering process of fraction (q) of HS and magnetic order (m) has become an interesting problem. Here it should be noted that the magnetic state is always metastable but not equilibrium unless the magnitude of the interaction is of the order of D in the models of SC. If D is so large that the magnetic state appears in equilibrium, the change of HS-LS is smooth and the first order phase transition does not takes place. The detailed properties of magnetic transition will be reported elsewhere.[38),39),68)] This feature of metastable magnetic state is compatible with the observation in Co-Fe PBA.

In the CT system, however, magnetic ordered state appears as an equilibrium state at a much lower temperature than the CT transition temperature. In order to explain this magnetic transition, we need to consider the special property of the CT system. Indeed, in the CT system, magnetic moments exist on B-sites even at low temperatures. Thus, if some mechanism exists to connect the magnetic moments, the magnetic order can be formed even in the low temperature configuration. One of the authors has proposed a mechanism that the thermal fluctuation of A-site could mediate the magnetic ordering between the B-sites.[65)] However, this mechanism has been found to be difficult at least in two dimensional systems,[66)] and several alternate origins of magnetic ordering are under investigation. In particular, it is possible that a quantum fluctuation helps the magnetic ordering which will be reported elsewhere.[67)]
